Conjunctivitis
A Systematic Review of Diagnosis and Treatment

Amir A. Azari, MD; Neal P. Barney, MD

Conjunctiva is a thin, translucent membrane lining the anterior part of the sclera and inside of the eyelids. It has 2 parts, bulbar and palpebral. The bulbar portion begins at the edge of the cornea and covers the visible part of the sclera; the palpebral part lines the inside of the eyelids (Figure 1). Inflammation or infection of the conjunctiva is known as conjunctivitis and is characterized by dilatation of the conjunctival vessels, resulting in hyperemia and edema of the conjunctiva, typically with associated discharge.1

Conjunctivitis affects many people and imposes economic and social burdens. It is estimated that acute conjunctivitis affects 6 million people annually in the United States.2 The cost of treating bacterial conjunctivitis alone was estimated to be $377 million to $857 million per year.2 Many US state health departments, irrespective of the underlying cause of conjunctivitis, require students to be treated with topical antibiotic eyedrops before returning to school.4 A majority of conjunctivitis patients are initially treated by primary care physicians rather than eye care professionals. Approximately 1% of all primary care office visits in the United States are related to conjunctivitis.5 Approximately 70% of all patients with acute conjunctivitis present to primary care and urgent care.6

The prevalence of conjunctivitis varies according to the underlying cause, which may be influenced by the patient’s age, as well as the season of the year. Viral conjunctivitis is the most common cause of infectious conjunctivitis both overall and in the adult population7-13 and is more prevalent in summer.14 Bacterial conjunctivitis is the second most common cause7-9,12,13 and is responsible for the majority (50%-75%) of cases in children14; it is observed more frequently from December through April.14 Allergic conjunctivitis is the most frequent cause, affecting 15% to 40% of the population,15 and is observed more frequently in spring and summer.14

IMPORTANCE Conjunctivitis is a common problem.

OBJECTIVE To examine the diagnosis, management, and treatment of conjunctivitis, including various antibiotics and alternatives to antibiotic use in infectious conjunctivitis and use of antihistamines and mast cell stabilizers in allergic conjunctivitis.

EVIDENCE REVIEW A search of the literature published through March 2013, using PubMed, the ISI Web of Knowledge database, and the Cochrane Library was performed. Eligible articles were selected after review of titles, abstracts, and references.

FINDINGS Viral conjunctivitis is the most common overall cause of infectious conjunctivitis and usually does not require treatment; the signs and symptoms at presentation are variable. Bacterial conjunctivitis is the second most common cause of infectious conjunctivitis, with most uncomplicated cases resolving in 1 to 2 weeks. Mattering and adherence of the eyelids on waking, lack of itching, and absence of a history of conjunctivitis are the strongest factors associated with bacterial conjunctivitis. Topical antibiotics decrease the duration of bacterial conjunctivitis and allow earlier return to school or work. Conjunctivitis secondary to sexually transmitted diseases such as chlamydia and gonorrhea requires systemic treatment in addition to topical antibiotic therapy. Allergic conjunctivitis is encountered in up to 40% of the population, but only a small proportion of these individuals seek medical help; itching is the most consistent sign in allergic conjunctivitis, and treatment consists of topical antihistamines and mast cell inhibitors.

CONCLUSIONS AND RELEVANCE The majority of cases in bacterial conjunctivitis are self-limiting and no treatment is necessary in uncomplicated cases. However, conjunctivitis caused by gonorrhea or chlamydia and conjunctivitis in contact lens wearers should be treated with antibiotics. Treatment for viral conjunctivitis is supportive. Treatment with antihistamines and mast cell stabilizers alleviates the symptoms of allergic conjunctivitis.

CME Quiz at jamanetworkcme.com and CME Questions 1732
Conjunctivitis can be divided into infectious and noninfectious causes. Viruses and bacteria are the most common infectious causes. Noninfectious conjunctivitis includes allergic, toxic, and cicatricial conjunctivitis, as well as inflammation secondary to immune-mediated diseases and neoplastic processes. The disease can also be classified into acute, hyperacute, and chronic according to the mode of onset and the severity of the clinical response. Furthermore, it can be either primary or secondary to systemic diseases such as gonorrhea, chlamydia, graft-vs-host disease, and Reiter syndrome, in which case systemic treatment is warranted.

It is important to differentiate conjunctivitis from other sight-threatening eye diseases that have similar clinical presentation and to make appropriate decisions about further testing, treatment, or referral. An algorithmic approach (Figure 2) using a focused ocular history along with a penlight eye examination may be helpful in diagnosis and treatment. Because conjunctivitis and many other ocular diseases can present as “red eye,” the differential diagnosis of red eye and knowledge about the typical features of each disease in this category are important (Table 1).

Methods

The literature published through March 2013 was reviewed by searching PubMed, the ISI Web of Knowledge database, and the Cochrane Library. The following keywords were used: bacterial conjunctivitis, viral conjunctivitis, allergic conjunctivitis, treatment of bacterial conjunctivitis, and treatment of viral conjunctivitis. No language restriction was applied. Articles published between March 2003 and March 2013 were initially screened. After review of titles, abstracts, text, and references for the articles, more were identified and screened. Articles and meta-analyses that provided evidence-based information about the cause, management, and treatment of various types of conjunctivitis were selected. A total of 86 articles were included in this review. The first study was published in 1982 and the last in 2012. A level of evidence was assigned to the recommendations presented in Table 2 and Table 3 with the American Heart Association grading system: "The strongest weight of evidence (A) is assigned if there are multiple randomized trials with large numbers of patients. An intermediate weight (B) is assigned if there are a limited number of randomized trials with small numbers of patients, careful analyses of non-randomized studies, or observational registries. The lowest rank of evidence (C) is assigned when expert consensus is the primary basis for the recommendation."
condition, including conjunctivitis. Eye discharge type and ocular symptoms can be used to determine the cause of the conjunctivitis. For example, a purulent or mucopurulent discharge is often due to bacterial conjunctivitis (Figure 3A and Figure 3B), whereas a watery discharge is more characteristic of viral conjunctivitis (Figure 3C). Itching is also associated with allergic conjunctivitis.

However, the clinical presentation is often nonspecific. Relying on the type of discharge and patient symptoms does not always lead to an accurate diagnosis. Furthermore, scientific evidence correlating conjunctivitis signs and symptoms with the underlying cause is often lacking. For example, in a study of patients with culture-positive bacterial conjunctivitis, 58% had itching, 65% had burning, and 35% had serous or no discharge at all, whereas epidemic keratoconjunctivitis is more severe and presents with watery discharge, hyperemia, chemosis, and ipsilateral lymphadenopathy.

Laboratory Investigations

Obtaining conjunctival cultures is generally reserved for cases of suspected infectious neonatal conjunctivitis, recurrent conjunctivitis, conjunctivitis recalcitrant to therapy, conjunctivitis presenting with severe purulent discharge, and cases suspicious for gonococcal or chlamydial infection. In-office rapid antigen testing is available for adenoviruses and has 89% sensitivity and up to 94% specificity. This test can identify the viral causes of conjunctivitis and prevent unnecessary antibiotic use. Thirty-six percent of conjunctivitis cases are due to adenoviruses, and one study estimated that in-office rapid antigen testing could prevent 1.1 million cases of inappropriate treatment with antibiotics, potentially saving $429 million annually.

Infectious Conjunctivitis

Viral Conjunctivitis

Epidemiology, Cause, and Presentation

Viruses cause up to 80% of all cases of acute conjunctivitis. The rate of clinical accuracy in diagnosing viral conjunctivitis is less than 50% compared with laboratory confirmation. Many cases are misdiagnosed as bacterial conjunctivitis.

Between 65% and 90% of cases of viral conjunctivitis are caused by adenoviruses, and they produce 2 of the common clinical entities associated with viral conjunctivitis, pharyngoconjunctival fever and epidemic keratoconjunctivitis. Pharyngoconjunctival fever is characterized by abrupt onset of high fever, pharyngitis, and bilateral conjunctivitis, and by periauricular lymph node enlargement, whereas epidemic keratoconjunctivitis is more severe and presents with watery discharge, hyperemia, chemosis, and ipsilateral lymphadenopathy. Lymphadenopathy is observed in up to 50%

of viral conjunctivitis cases and is more prevalent in viral conjunctivitis compared with bacterial conjunctivitis.49

Prevention and Treatment
Viral conjunctivitis secondary to adenoviruses is highly contagious, and the risk of transmission has been estimated to be 10% to 50%.6,34 The virus spreads through direct contact via contaminated fingers, medical instruments, swimming pool water, or personal items; in one study, 46% of infected people had positive cultures grown from swabs of their hands.69 Because of the high rates of transmission, hand washing, strict instrument disinfection, and isolation of the infected patients from the rest of the clinic has been advocated.70 Incubation and communicability are estimated to be 5 to 12 days and 10 to 14 days, respectively.34

Although no effective treatment exists, artificial tears, topical antihistamines, or cold compresses may be useful in alleviating some of the symptoms (Table 2).16,50 Available antiviral medications are not useful16,50 and topical antibiotics are not indicated.18 Topical antibiotics do not protect against secondary infections, and their use may complicate the clinical presentation by causing allergy and toxicity, leading to delay in diagnosis of other possible ocular diseases.49 Use of antibiotic eyedrops can increase the risk of spreading the infection to the other eye from contaminated droppers.49 Increased resistance is also of concern with frequent use of antibiotics.6 Patients should be referred to an ophthalmologist if symptoms do not resolve after 7 to 10 days because of the risk of complications.1

Herpes Conjunctivitis
Herpes simplex virus comprises 1.3% to 4.8% of all cases of acute conjunctivitis.9-12 Conjunctivitis caused by the virus is usually unilateral. The discharge is thin and watery, and accompanying vescular eyelid lesions may be present. Topical and oral antivirals are recommended (Table 2) to shorten the course of the disease.16 Topical corticosteroids should be avoided because they potentiate the virus and may cause harm.16,71

Herpes zoster virus, responsible for shingles, can involve ocular tissue, especially if the first and second branches of the trigeminal nerve are involved. Eyelids (45.8%) are the most common site of ocular involvement, followed by the conjunctiva (41.1%).72 Corneal complication and uveitis may be present in 38.2% and 19.1% of cases, respectively.72 Patients with suspected eyelid or eye involvement or those presenting with Hutchinson sign (vesicles at the tip of the nose, which has high correlations with corneal involvement) should be referred for a thorough ophthalmic evaluation. Treatment usually consists of a combination of oral antivirals and topical steroids.73

Bacterial Conjunctivitis
Epidemiology, Cause, and Presentation
The incidence of bacterial conjunctivitis was estimated to be 135 in 10 000 in one study.7 Bacterial conjunctivitis can be contracted directly from infected individuals or can result from abnormal proliferation of the native conjunctival flora.17 Contaminated fingers,16 ocular-lateral spread;16 and contaminated fomites48 are common routes of transmission. In addition, certain conditions such as compromised tear production, disruption of the natural epithelial barrier, abnormality of adnexal structures, trauma, and immunosuppressed status predispose to bacterial conjunctivitis.56 The most common pathogens for bacterial conjunctivitis in adults are staphylococcal species, followed by Streptococcus pneumoniae and Haemophilus influenzae.41 In children, the disease is often caused by H influenzae, S pneumoniae, and Moraxella catarrhalis.41 The course of the disease usually lasts 7 to 10 days (Figure 3).62

Figure 3. Characteristic Appearance of Bacterial and Viral Conjunctivitis

A. Bacterial conjunctivitis characterized by mucopurulent discharge and conjunctival hyperemia. B. Severe purulent discharge seen in hyperacute bacterial conjunctivitis secondary to gonorrhea. C. Intensely hyperemic response with thin, watery discharge characteristic of viral conjunctivitis. Images reproduced with permission. © 2013 American Academy of Ophthalmology.
Hyperacute bacterial conjunctivitis presents with a severe copious purulent discharge and decreased vision (Figure 3). There is often accompanying eyelid swelling, eye pain on palpation, and preauricular adenopathy. It is often caused by Neisseria gonorrhoeae and carries a high risk for corneal involvement and subsequent corneal perforation. Treatment for hyperacute conjunctivitis secondary to N gonorrhoeae consists of intramuscular ceftriaxone, and concurrent chlamydial infection should be managed accordingly.

Chronic bacterial conjunctivitis is used to describe any conjunctivitis lasting more than 4 weeks, with Staphylococcus aureus, Moraxella lacunata, and enteric bacteria being the most common causes in this setting; ophthalmologic consultation should be sought for management.

Signs and symptoms include red eye, purulent or mucopurulent discharge, and chemosis (Figure 3). The period of incubation and communicability is estimated to be 1 to 7 days and 2 to 7 days, respectively. Bilateral matting of the eyelids and adherence of the eyelids, lack of itching, and no history of conjunctivitis are strong positive predictors of bacterial conjunctivitis. Severe purulent discharge should always be cultured and gonococcal conjunctivitis should be considered (Figure 3B). Conjunctivitis not responding to standard antibiotic therapy in sexually active patients warrants a chlamydial evaluation. The possibility of bacterial keratitis is high in contact lens wearers, who should be treated with topical antibiotics and referred to an ophthalmologist. A patient wearing contact lenses should be asked to immediately remove them.

Use of Antibiotics in Bacterial Conjunctivitis

At least 60% of cases of suspected or culture-proven acute bacterial conjunctivitis are self-limiting within 1 to 2 weeks of presentation. Although topical antibiotics reduce the duration of the disease, no differences have been observed in outcomes between treatment and placebo groups. In a large meta-analysis, consisting of a review of 3673 patients in 11 randomized clinical trials, there was an approximately 10% increase in the rate of clinical improvement compared with that for placebo for patients who received either 2 to 5 days or 6 to 10 days of antibiotic treatment compared with the placebo. No serious sight-threatening outcomes were reported in any of the placebo groups. Some highly virulent bacteria, such as S pneumoniae, N gonorrhoeae, and H influenzae, can penetrate an intact host defense more easily and cause more serious damage.

Topical antibiotics seem to be more effective in patients who have positive bacterial culture results. In a large systemic review, they were found to be effective at increasing both the clinical and microbiological cure rate in the group of patients with culture-proven bacterial conjunctivitis, whereas only an improved microbial cure rate was observed in the group of patients with clinically suspected bacterial conjunctivitis. Other studies found no significant difference in clinical cure rate when the frequencies of the administered antibiotics were slightly changed.

Choices of Antibiotics

All broad-spectrum antibiotic eyedrops seem in general to be effective in treating bacterial conjunctivitis. There are no significant differences in achieving clinical cure between any of the broad-spectrum topical antibiotics. Factors that influence antibiotic choice are local availability, patient allergies, resistance patterns, and cost. Initial therapy for acute nonsevere bacterial conjunctivitis is listed in Table 2.

Alternatives to Immediate Antibiotic Therapy

To our knowledge, no studies have been conducted to evaluate the efficacy of ocular decongestant, topical saline, or warm compresses for treating bacterial conjunctivitis. Topical steroids should be avoided because of the risk of potentially prolonging the course of the disease and potentiating the infection.

Summary of Recommendations for Managing Bacterial Conjunctivitis

In conclusion, benefits of antibiotic treatment include quicker recovery, decrease in transmissibility, and early return to school. Simultaneously, adverse effects are absent if antibiotics are not used in uncomplicated cases of bacterial conjunctivitis. Therefore, no treatment, a wait-and-see policy, and immediate treatment all appear to be reasonable approaches in cases of uncomplicated conjunctivitis. Antibiotic therapy should be considered in cases of purulent or mucopurulent conjunctivitis and for patients who have distinct discomfort, who wear contact lenses, who are immunocompromised, and who have suspected chlamydia and gonococcal conjunctivitis.

Special Topics in Bacterial Conjunctivitis

Methicillin-Resistant S aureus Conjunctivitis

It is estimated that 3% to 64% of ocular staphylococcal infections are due to methicillin-resistant S aureus conjunctivitis; this condition is becoming more common and the organisms are resistant to many antibiotics. Patients with suspected cases need to be referred to an ophthalmologist and treated with fortified vancomycin.

Chlamydial Conjunctivitis

It is estimated that 1.8% to 5.6% of all acute conjunctivitis is caused by chlamydia, and the majority of cases are unilateral and have concurrent genital infection. Conjunctival hyperemia, mucopurulent discharge, and lymphoid follicle formation are hallmarks of this condition. Discharge is often purulent or mucopurulent. However, patients more often present with mild symptoms for weeks to months. Up to 54% of men and 74% of women have concurrent genital chlamydial infection. The disease is often acquired via ocular-genital spread or other intimate contact with infected individuals; in newborns the eyes can be infected after vaginal delivery by infected mothers. Treatment with systemic antibiotics such as oral azithromycin and doxycycline is efficacious (Table 2); patients and their sexual partners must be treated and a coinfection with gonorrhea must be investigated. No data support the use of topical antibiotic therapy in addition to systemic treatment. Infants with chlamydial conjunctivitis require systemic therapy because more than 50% can have concurrent lung, nasopharynx, and genital tract infection.

Gonococcal Conjunctivitis

Conjunctivitis caused by N gonorrhoeae is a frequent source of hyperacute conjunctivas in neonates and sexually active adults and young adolescents. Treatment consists of both topical and oral antibiotics. Neisseria gonorrhoeae is associated with a high risk of corneal perforation.
Conjunctivitis Secondary to Trachoma
Trachoma is caused by *Chlamydia trachomatis* subtypes A through C and is the leading cause of blindness, affecting 40 million people worldwide in areas with poor hygiene.79,80 Mucopurulent discharge and ocular discomfort may be the presenting signs and symptoms in this condition. Late complications such as scarring of the eyelid, conjunctiva, and cornea may lead to loss of vision. Treatment with a single dose of oral azithromycin (20 mg/kg) is effective. Patients may also be treated with topical antibiotic ointments for 6 weeks (ie, tetracycline or erythromycin). Systemic antibiotics other than azithromycin, such as tetracycline or erythromycin for 3 weeks, may be used alternatively.79,80

Noninfectious Conjunctivitis

Allergic Conjunctivitis
Prevalence and Cause
Allergic conjunctivitis is the inflammatory response of the conjunctiva to allergens such as pollen, animal dander, and other environmental antigens15 and affects up to 40% of the population in the United States55; only about 10% of individuals with allergic conjunctivitis seek medical attention, and the entity is often underdiagnosed.81 Redness and itching are the most consistent symptoms.15 Seasonal allergic conjunctivitis comprises 90% of all allergic conjunctivitis in the United States.82

Treatment
Treatment consists of avoidance of the offending antigen52 and use of saline solution or artificial tears to physically dilute and remove the allergens.15 Topical decongestants, antihistamines,52 mast cell stabilizers,52 nonsteroidal anti-inflammatory drugs,53,54 and corticosteroids82 may be indicated. In a large systemic review, both antihistamines and mast cell stabilizers were superior to placebo in reducing the symptoms of allergic conjunctivitis; researchers also found that antihistamines were superior to mast cell stabilizers in providing short-term benefits.52 Long-term use of the antihistamine antazoline and the vasoconstrictor naphazoline should be avoided because they both can cause rebound hyperemia.52 Steroids should be used with caution and judiciously. Topical steroids are associated with formation of cataract and can cause an increase in eye pressure, leading to glaucoma.

Drug-, Chemical-, and Toxin-Induced Conjunctivitis
A variety of topical medications such as antibiotic eyedrops, topical antiviral medications, and lubricating eyedrops can induce allergic conjunctival responses largely because of the presence of benzalkonium chloride in eye drop preparations.83 Cessation of receiving the offending agent leads to resolution of symptoms.16

Systemic Diseases Associated With Conjunctivitis
A variety of systemic diseases, including mucous membrane pemphigoid, Sjögren syndrome, Kawasaki disease,89 Stevens-Johnson syndrome,85 and carotid cavernous fistula,86 can present with signs and symptoms of conjunctivitis, such as conjunctival redness and discharge. Therefore, the above causes should be considered in patients presenting with conjunctivitis. For example, patients with low-grade carotid cavernous fistula can present with chronic conjunctivitis recalcitrant to medical therapy, which, if left untreated, can lead to death.

Ominous Signs
As recommended by the American Academy of Ophthalmology,16 patients with conjunctivitis who are evaluated by nonophthalmologist health care practitioners should be referred promptly to an ophthalmologist if any of the following develops: visual loss, moderate or severe pain, severe purulent discharge, corneal involvement, conjunctival scarring, lack of response to therapy, recurrent episodes of conjunctivitis, or history of herpes simplex virus eye disease. In addition, the following patients should be considered for referral: contact lens wearers, patients requiring steroids, and those with photophobia. Patients should be referred to an ophthalmologist if there is no improvement after 1 week.1

Importance of Not Using Antibiotic/Steroid Combination Drops
Steroid drops or combination drops containing steroids should not be used routinely. Steroids can increase the latency of the adenoviruses, therefore prolonging the course of viral conjunctivitis. In addition, if an undiagnosed corneal ulcer secondary to herpes, bacteria, or fungus is present, steroids can worsen the condition, leading to corneal melt and blindness.

Conclusions
Approximately 1% of all patient visits to a primary care physician are conjunctivitis related, and the estimated cost of the bacterial conjunctivitis alone is $377 million to $857 million annually.3,5 Relying on the signs and symptoms often leads to an inaccurate diagnosis. Nonherpetic viral conjunctivitis followed by bacterial conjunctivitis is the most common cause for infectious conjunctivitis.7-13 Allergic conjunctivitis affects nearly 40% of the population, but only a small proportion seeks medical care.15,81 The majority of viral conjunctivitis cases are due to adenovirus.59 There is no role for the use of topical antibiotics in viral conjunctivitis, and they should be avoided because of adverse treatment effects.6,49 Using a rapid antigen test to diagnose viral conjunctivitis and avoid inappropriate use of antibiotics is an appropriate strategy.68 Bacterial pathogens are isolated in only 50% of cases of suspected conjunctivitis,18 and at least 60% of bacterial conjunctivitis (clinically suspected or culture proven) is self-limited without treatment.14 Cultures are useful in cases that do not respond to therapy, cases of hyperacute conjunctivitis, and suspected chlamydial conjunctivitis.16 Treatment with topical antibiotics is usually recommended for contact lens wearers, those with mucopurulent discharge and eye pain, suspected cases of chlamydial and gonococcal conjunctivitis, and patients with preexisting ocular surface disease.14,18 The advantages of antibiotic use include early resolution of the disease,19 early return to work or school,4,14 and the possibility of decreased complications from conjunctivitis.14 The majority of cases of allergic conjunctivitis are due to seasonal allergies.82 Antihistamines, mast cell inhibitors, and topical steroids (in selected cases) are indicated for treating allergic conjunctivitis.82 Steroids must be used judiciously and only after a thorough ophthalmologic examination has been performed to

rule out herpetic infection or corneal involvement, both of which can worsen with steroids.16,71

Physicians must be vigilant to not overlook sight-threatening conditions with similarities to conjunctivitis, as summarized in Table 1.

ARTICLE INFORMATION
Conflict of Interest Disclosures: All authors have completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest and none were reported.

Funding/Support: This work was supported by National Institutes of Health (NIH) grant P30-EY01665 (Core Grant for Vision Research) and an unrestricted department award from Research to Prevent Blindness. The project was also supported by the Clinical and Translational Science Award program through the NIH National Center for Advancing Translational Sciences, grant UL1TR000427.

Role of the Sponsor: The sponsors played no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript, and decision to submit the manuscript for publication.

Correction: This article was corrected on December 5, 2013, to correct the dosage of acyclovir for herpes in Table 2 and to update the algorithm in Figure 2 to include viral conjunctivitis.

Submissions: We encourage authors to submit papers for consideration as a Review. Please contact Mary McGrae McDermott, MD, at mmd608@northwestern.edu.
